Keywords: Boundary element method; DRM-MD; Unsaturated flow.

Abstract. A numerical single-phase model for unsteady state unsaturated flow has been derived and solved using the boundary element method (BEM). BEM procedures have had a relatively restricted development due to the limitation of the conventional BEM to deal with the highly non-linear governing equations. Here, the governing equation has been represented as a non-homogeneous Laplace equation, and the non-homogeneous part has been dealt with by using the dual reciprocity method (DRM). The soil-water characteristic curve according to a van Genuchten approach was employed. The developed scheme was implemented in a 3D code and applied to solution of upward and downward infiltration in clay showing good agreement with numerical solutions previously reported in open literature.
1 INTRODUCTION

Modelling of unsaturated flow in porous media is applied in a number of different areas. Some areas of interest include hydrology, environmental protection and remediation and disposal of hazardous waste in underground repositories. In this work a numerical model for unsaturated flow where both phases, water and air, are modelled is developed. Such model could be of importance for solution of the problem of wetting of clay in underground repositories where the air cannot escape freely during the wetting of the clay, a process which may increase the air pressure slowing down the actual wetting process.

Unlike the FEM and other domain based methods, which have been widely applied to the problem of unsaturated flow, BEM procedures have had a relatively restricted development due to the limitation of the conventional BEM to deal with the highly non-linear governing equations. Early work on the solution of the Richard’s equation used linearization schemes (Philip, 1969, 1989; Raats, 1970; Pullan, 1988, 1990), but Taigbenu and Onyejekwe (1995) pointed out that this lead to formulations that can at at least accommodate weak variations of medium properties. For instance, Martinez and Mc Tigue (1991) developed an effective solution technique, provided the domain is homogeneous, by applying a Kirchhoff transformation to the steady form of the Richard’s equation and using an exponential model for the hydraulic conductivity. In order to implement the procedure to problems defined in piecewise homogeneous domains, Martinez (1992) had to employ domain subdivision, in which case non-linear conditions appear at the interfaces of subdomains with different properties. Taigbenu and Onyejekwe (1995) were the first ones who solved the transient Richard’s equation without either linearizing or using a special case of soil constitutive relation. They used a BEM procedure known as the Green element method (GEM) (Taigbenu, 1999). The GEM subdivides the domain in large number of sub-regions resulting in a mesh that looks like a FEM mesh. It uses the fundamental solution of the Laplace equation and domain integration in each subdomain. The matrix of coefficients of the resulting system of equations is banded and the procedure is apt to cope with non-homogeneous domains.

In this work, the model is solved by using the BEM dual reciprocity - multi domain approach (DRM-MD), which has shown good stability for solving non-linear problems in the past. The extension of the DRM-MD to different cases of unsaturated flow has been accomplished by Natalini (2005) and Samardzioska and Popov (2006). The DRM-MD shall be introduced in section 5.

2 GOVERNING EQUATIONS FOR FLOW IN UNSATURATED POROUS MEDIA

In this section a quick derivation of the governing equations is presented. It is considered that each phase occupies part of the domain and follows its own set of tortuous paths. A detailed treatment of the theory of flow in unsaturated media is given by Bear and Verruijt (1987) and Helmig (1997).

2.1 Equation for the water phase

The mass balance equation is given as

\[ \frac{\partial (n \rho_w S_w)}{\partial t} + \vec{V} \cdot \rho_w \vec{q}_w = 0 \]  

where \( n \) is the porosity, \( \rho_w \) is the water density and \( S_w \) is the water saturation. \( S_w \) is defined as the relation of the volume of water in a representative elementary volume (REV) and the volume of voids in the REV. \( S_w \) ranges from zero to one.
The specific discharge is defined using the Darcy law

\[ \bar{q}_w = -\frac{k_w}{\mu_w} \left( \vec{v}_p w - \rho_w g \vec{v} z \right) \quad (2) \]

where \( k_w \) is the effective permeability for water (a function of \( S_w \)), \( \mu_w \) is the dynamic viscosity of water, \( p_w \) is the water pressure and \( z \) is the elevation.

By substituting (2) into (1) and considering that \( n \) and \( \rho_w \) are constant, (1) can take the following form

\[ \nabla^2 p_w = \frac{\mu_w}{k_w} n \frac{\partial S_w}{\partial t} - \frac{1}{k_w} \vec{v} k_w \cdot \vec{v} p_w + \frac{\rho_w g}{k_w} \vec{v} k_w \cdot \vec{v} z \quad (3) \]

The water relative permeability is defined as

\[ k_{rw}(S_w) = \frac{k_w(S_w)}{k_w(1)} \quad (4) \]

and

\[ k_w(1) = \frac{\mu_w K_w}{\rho_w g} \quad (5) \]

where \( K_w \) is the hydraulic conductivity for water, yielding

\[ k_w(S_w) = \frac{k_{rw}(S_w) K_w \mu_w}{\rho_w g} \quad (6) \]

By substituting (6) into (3), the equation for the water phase is obtained as

\[ \nabla^2 p_w = \frac{n \rho_w g}{k_{rw} K_w} \frac{\partial S_w}{\partial t} - \frac{1}{k_{rw}} \vec{v} k_{rw} \cdot \vec{v} p_w + \frac{\rho_w g}{k_{rw}} \vec{v} k_{rw} \cdot \vec{v} z \quad (7) \]

Note that it is possible to use equation (3) for the water phase, however (7) is a more suitable form since \( k_{rw} \) is non-dimensional and ranges from 0 to 1. Conversely, \( k_w \) has dimensions, which makes its order of magnitude dependant on the scale factors, which can produce higher errors when the term \( \frac{1}{k_w} \vec{v} k_w \) is calculated rather than \( \frac{1}{k_{rw}} \vec{v} k_{rw} \).

2.2 Equation for the air phase

The starting point for development of the equation for air phase is the mass balance equation:

\[ \frac{\partial (n \rho_a S_a)}{\partial t} + \vec{v} \cdot \rho_a \vec{q}_a = 0 \quad (8) \]

combined with the Darcy law

\[ \vec{q}_a = -\frac{k_a}{\mu_a} \left( \vec{v} p_a - \rho_a g \vec{v} z \right) \quad (9) \]
where the nomenclature analogous to the one in (1) and (2), the sub-index ‘a’ identifying air properties. Note that

\[ S_w + S_a = 1 \]  

(10)

By substituting (9) into (8), considering \( n \) to be constant and neglecting the gravitational term \( \rho_a g \nabla z \), and by using \( \frac{k_a}{\mu_a} = \frac{k_{ra} K_a}{\rho_a g} \), the following equation is obtained

\[ n \frac{\partial (\rho_a S_a)}{\partial t} - \frac{K_a}{g} \nabla \cdot (k_{ra} \nabla p_a) = 0 \]

(11)

Further, developing both terms in (11), considering that \( \rho_a \) is linked to \( p_a \) through the equation of state and rearranging the equation yields

\[ \nabla^2 p_a = \frac{g}{k_{ra} K_a} \left[ n \frac{R'}{T} \left( S_a \frac{\partial p_a}{\partial t} + p_a \frac{\partial S_a}{\partial t} \right) - \frac{K_a}{g} \left( \nabla k_{ra} \cdot \nabla p_a \right) \right] \]

(12)

The derivative in time of the saturation appearing in (7) and (12) can be handled in the following way:

\[ \frac{\partial S_w}{\partial t} = \frac{\partial S_w}{\partial p_c} \frac{\partial p_c}{\partial t} = \frac{dS_w}{dp_c} \frac{\partial p_c}{\partial t} \frac{\partial p_\gamma}{\partial t} \]

(13)

where subscript \( \gamma \) stands for “w” or “a” depending on the equation that is solved. Taking into account that the capillary pressure can be expressed as \( p_c = p_a - p_w \), it is obvious that \( \partial p_\gamma / \partial p_\gamma = (1 \text{ or } -1) \). If furthermore we use (10) to eliminate \( S_a \), the final equations for water and air become

\[ \nabla^2 p_w = -\frac{n \rho_w g}{k_{rw} K_w} \frac{\partial S_w}{\partial p_w} \frac{\partial p_w}{\partial t} - \frac{1}{k_{rw}} \nabla k_{rw} \cdot \nabla p_w + \frac{\rho_w g}{k_{rw}} \nabla k_{rw} \cdot \nabla z \]

(14)

and

\[ \nabla^2 p_a = \frac{g}{k_{ra} K_a} \left[ \frac{n}{R'T} \left( 1 - S_w \right) - p_a \frac{\partial S_w}{\partial p_a} \frac{\partial p_a}{\partial t} - \frac{K_a}{g} \left( \nabla k_{ra} \cdot \nabla p_a \right) \right] \]

(15)

Equations (14) and (15) are the equations to be solved by the code, being \( p_w \) and \( p_a \) the unknown potential fields. The constants needed in the model are \( g, \rho_w, n, K_w, K_a, R' \) and \( T \) while \( k_{rw}, S_w \) and \( k_{ra} \) are functions of \( p_w \) and \( p_a \). The functions linking the potential fields and \( k_{rw}, S_w \) and \( k_{ra} \) variables are given by the soil water retention curve.

3 SOIL WATER RETENTION CURVE

The soil water retention curve describes the relation between the capillary pressure, \( p_c \), and \( S_w \). There are several functions that have been proposed; among the most popular for the air-water system are those given by Leverett (1941), Brooks and Corey (1964) and van Genuchten (1980). Recently Vogel et al. (1988, 2001) suggested the use of the following relation:
where $S_m$ is a fictitious extrapolated parameter; $S_m > 1$, and $p_s$ is called the minimum capillary pressure. As (16) has evolved from the van Genuchten’s model, here it will be referred as the modified van Genuchten’s model. The modified Van Genuchten’s relative water permeabilities as a function of saturations are

$$k_{rw} = \sqrt{S_e} \left( \frac{1 - F(S_e)}{1 - F(1)} \right)^2$$

and

$$k_{ra} = (1 - S_e)^{1/2} \left( \frac{F(S_e) - F(1)}{1 - F(1)} \right)^2$$

(17)

where

$$F(S_e) = \left( 1 - S_e^{1/m} \right)^m$$

and

$$S_e^* = \frac{1 - S_{w0}}{S_m - S_{w0} - S_{a0}} S_e$$

(18)

and

$$S_e = \frac{S_{w} - S_{w0}}{1 - S_{w0} - S_{a0}}$$

(19)

Equation (16) has been originally proposed in terms of water contents; here it is modified in order to match with the definition (19), which takes into account $S_{a0}$, and the relative permeability of the air phase. Equations (16) – (19) will be referred to as the modified Van Genuchten model (VGM). The modified VGM eliminates numerical instabilities appearing near saturation and this formulation is further used in the numerical examples in section 6.

4 SOLVING THE SYSTEM OF EQUATIONS

When considering the simultaneous flow of both the water and the air in the unsaturated zone, the system of equations is represented by (14) and (15) together with those coming from the soil water model. Though the numerical model is developed for the case of variable air pressure, further in this work the air pressure is considered to be constant and equal to the atmospheric pressure. Therefore, in the examples presented here only (14) is solved; which is equivalent to solving the Richard’s equation.

The code developed obtains solutions at different timesteps by using a linear time finite difference approximation. As the equations are non-linear, in each timestep an iterative procedure is applied. The code starts by calculating $p_c$ from the initial conditions of the problem, then $S_w$ and $k_{rw}$ are calculated and finally (14) is solved. In the next iteration, with the obtained value of $p_w$, a new value for $p_c$ is calculated, then $S_w$ and $k_{rw}$ are recalculated and (14) is solved again. The process is repeated until convergence is reached within each timestep.

The derivative of $S_w$ in respect to $p_c$ appearing in the equations will depend on the soil water retention model used and for the modified VGM it can be obtained as
\[
\frac{\partial S_w}{\partial p_c} = \begin{cases} 
- \frac{n \alpha_m (S_m - S_w - S_{\alpha 0}) (ap_c)^{n-1}}{(1 + (ap_c)^n)^{m+1}} & \text{when } p_c > p_s \\
0 & \text{when } p_c \leq p_s 
\end{cases} 
\] (20)

### 5 BEM DRM-MD IMPLEMENTATION FOR THE WATER PHASE

The dual reciprocity method (DRM), which was introduced by Nardini and Brebbia (1983), is acknowledged to be one of the most effective boundary element method (BEM) techniques for transforming domain integrals into boundary integrals.

Popov and Power implemented a scheme using domain subdivision in conjunction with the DRM to avoid domain integration and called it the Dual Reciprocity Method – Multi-Domain approach (DRM-MD). The initial problem solved using this formulation was the flow of a mixture of gases through a porous media (Popov and Power, 1999a, 2000; Popov, Power and Baldasano, 1998). The DRM-MD has also been applied to linear and non-linear advection-diffusion problems (Popov and Power, 1999b), driven cavity flow of Navier-Stokes equations (Florez and Power, 2002a), non-Newtonian fluids (Florez and Power, 2002b), and flow of polymers inside mixers with complex geometries (Florez, 2001). Though the above applications are two-dimensional (2D), recently the technique has been applied to three-dimensional (3D) problems by Natalini and Popov (2006, 2007) and Peratta and Popov (2006, 2007).

DRM-MD does not suffer the two main problems related to standard DRM; the systems of equations produced by DRM-MD are sparse and well conditioned, and the number and position of DRM nodes is usually not critical, since small sub-domains usually require no or few interior DRM nodes.

Starting from a Poisson-like governing equation

\[ \nabla^2 u(x,t) = b(u,x,t) \] (21)

where \( u(x,t) \) is a scalar field (potential field), \( b(u,x,t) \) is the non-homogeneous term and \( x \) is a position vector in the domain with components \( x_i \). After applying the DRM approach (for more details see Partridge et al., 1992), the following equation is obtained

\[
\lambda(x)u(x) + \int_{\Gamma} q^*(x,y)u(y)d\Gamma_y - \int_{\Gamma} u^*(x,y)q(y)d\Gamma_y \equiv \\
\sum_{k=1}^{J+i} \left\{ \alpha_k \left( \lambda(x)\hat{u}(x,z^k) + \int_{\Gamma} q^*(x,y)\hat{u}(y,z^k)d\Gamma_y - \int_{\Gamma} u^*(x,y)\hat{q}(y,z^k)d\Gamma_y \right) \right\} 
\] (22)

where \( u^*(x,y) \) is the fundamental solution of the Laplace equation, \( q(y) = \partial u(y)/\partial n \), \( q^*(x,y) = \partial u^*(x,y)/\partial n \) and \( n \) is the unit vector normal to the boundary of the domain. The constant \( \lambda(x) \) has values between 1 and 0, being equal to 1/2 on smooth parts of boundaries and being equal to 1 for points inside the domain. Constants \( \alpha_k \) are unknown coefficients and the DRM approximation is applied to \( J \) nodes on the boundary \( \Gamma \) of the domain and \( I \) nodes inside the domain \( \Omega \).

After application of collocation technique to all boundary nodes, (22) can be written in terms of four matrices, \( \mathbf{H}, \mathbf{G}, \mathbf{\hat{U}} \) and \( \mathbf{\hat{Q}} \) which depend only on the geometry of the problem.
\[ Hu - Gq = (\tilde{H} - \tilde{Q})\alpha \]  

(23)

Since the non-homogeneous term \( b \) in the DRM is expressed in the following form

\[ b = F\alpha \]  

(24)

after expressing \( \alpha \) in terms of \( b \), the following equation is obtained

\[ Hu - Gq = (\tilde{H} - \tilde{Q})F^{-1}b \]  

(25)

The DRM integral formulation for \( p_w \) is obtained by replacing the non-homogeneous term in (14) into (25)

\[
\sum_{j=1}^{n} h_{ij} p_{wj} - \sum_{j=1}^{n} g_{ij} q_{wj} = \sum_{j=1}^{n} s_{ij} \left[ -\frac{n \rho_w g}{k_{rwj}} \frac{\partial \tilde{S}_{wj}}{\partial t} \frac{\partial p_{wj}}{\partial t} - \frac{1}{k_{w}} \left( \frac{\partial \tilde{k}_{rwj}}{\partial x} \frac{\partial p_{wj}}{\partial x} + \frac{\partial \tilde{k}_{rwj}}{\partial y} \frac{\partial p_{wj}}{\partial y} + \frac{\partial \tilde{k}_{rwj}}{\partial z} \frac{\partial p_{wj}}{\partial z} \right) \right] + \sum_{j=1}^{n} s_{ij} \frac{\rho_w g}{k_{rwj}} \frac{\partial \tilde{k}_{rwj}}{\partial \tilde{z}}
\]  

(26)

where \( s_{ij} \) is the matrix \((\tilde{H} - \tilde{Q})F^{-1}\) and \( \tilde{k}_{rwj} \) and \( \tilde{S}_{wj} / \tilde{p}_c \) are calculated using values of \( p_a = p_{atm} \) (atmospheric pressure) and \( p_w \) coming from the previous iteration, which will be denoted by \( \tilde{p}_w \) from here on.

\[ \frac{\partial p_{wj}}{\partial x} \]  

and all the others partial derivatives are obtained by applying the DRM approximation (24) which in index notation is given as

\[ \frac{\partial p_{wj}}{\partial x} = \sum_{k=1}^{n} \sum_{l=1}^{n} \frac{\partial f_{jl}}{\partial x} f_{lk}^{-1} p_{wk} \]  

(27)

The time discretization is based on the implicit/explicit Euler method

\[ p_w = (1 - \theta_{p_w}) p_w^{m} + \theta_{p_w} p_w^{m+1} \]  

(28)

\[ q_w = (1 - \theta_{q_w}) q_w^{m} + \theta_{q_w} q_w^{m+1} \]  

(29)

The time derivative is approximated using a finite-difference scheme

\[ \frac{\partial p_w}{\partial t} = \frac{1}{\Delta t} (p_w^{m+1} - p_w^{m}) \]  

(30)

By applying (27) – (30), (26) can be recast as

\[
\begin{pmatrix}
0_{p_w} H + \frac{\tilde{R}_w}{\Delta t} + 0_{p_w} \tilde{T}_w
\end{pmatrix} p_w^{m+1} - \theta_{q_w} G q_w^{m+1} = \left[ \begin{pmatrix}
0_{p_w} - 1
\end{pmatrix} \left( H + \tilde{T}_w \right) + \frac{\tilde{R}_w}{\Delta t} \right] p_w^{m} + (1 - \theta_{q_w}) G q_w^{m} + \rho_w g S \tilde{v}
\]  

(31)
where \( \tilde{R}_w \) is a matrix of components

\[
\tilde{r}_{wij} = s_{ij} \frac{n \rho_w g}{k_{rwj} K_w} \frac{\partial \tilde{\rho}}{\partial p_c} \tag{32}
\]

and \( \tilde{T}_w \) is defined as

\[
\tilde{T}_w = \left( \tilde{D}_x \frac{\partial F}{\partial x} F^{-1} + \tilde{D}_y \frac{\partial F}{\partial y} F^{-1} + \tilde{D}_z \frac{\partial F}{\partial z} F^{-1} \right) \tag{33}
\]

where \( \tilde{D}_x \) has components

\[
d_{ij} = s_{ij} \frac{1}{k_{rwj}} \frac{\partial \tilde{K}_{rwj}}{\partial x} \tag{34}\]

and similar for \( \tilde{D}_y \) and \( \tilde{D}_z \) matrices. The components of vector \( \tilde{v} \) are defined as

\[
\tilde{v}_j = \frac{1}{k_{rwj}} \frac{\partial \tilde{K}_{rwj}}{\partial z} \tag{35}\]

The interface conditions between two sub-domains for pressure and flux state that the pressure and the flux must preserve continuity. In the case of pressure the interface conditions result in the following equation

\[
p_{w1} = p_{w2} \tag{36}\]

In the case of flux the interface conditions are equivalent to applying the mass conservation principle and can be derived starting from the flux of water through the interface per unit surface and unit time for both interfaces as given below

\[
Q_1 = \tilde{q}_{w1} \cdot \tilde{n}_1 \quad \text{and} \quad Q_2 = \tilde{q}_{w2} \cdot \tilde{n}_2 \tag{37}\]

where \( \tilde{n}_1 \) and \( \tilde{n}_2 \) are the unit normal vectors to the interface calculated from \( \Omega_1 \) and \( \Omega_2 \) respectively. As \( \tilde{q}_{w1} = \tilde{q}_{w2} \) and \( \tilde{n}_1 = -\tilde{n}_2 \) the following is valid

\[
Q_1 = -Q_2 \tag{38}\]

Further considering that

\[
Q_1 = -\frac{k_{w1}}{\mu_w} q_{w1} + \frac{k_{w1}}{\mu_w} \rho_w g n_{z1} \quad \text{and} \quad Q_2 = -\frac{k_{w2}}{\mu_w} q_{w2} + \frac{k_{w2}}{\mu_w} \rho_w g n_{z2} \tag{39}\]

where \( n_{z1} \) is the z-component of \( \tilde{n}_1 \) and \( n_{z2} \) is the z-component of \( \tilde{n}_2 \). Finally, the matching condition for flux is obtained as

\[
q_{w2} = -\frac{k_{rw1} K_{w1}}{k_{rw2} K_{w2}} q_{w1} - \frac{k_{rw1} K_{w1} - k_{rw2} K_{w2}}{k_{rw2} K_{w2}} \rho_w g n_{z2} \tag{40}\]

or
6 NUMERICAL EXAMPLES

All the examples presented here use discontinuous elements combined with the augmented thin plate spline function as approximation function in the DRM approximation with no internal DRM nodes. The parameters \( \theta_p \) and \( \theta_q \) in equations (28) and (29) were set equal to 1, consequently the time discretization scheme becomes implicit Euler type.

6.1 CASE 1: Upward infiltration in clay

The first case simulates infiltration in a 1m long clay column that initially is assumed to be in equilibrium with an imposed water pressure, \( p_w \), of zero Pa at the bottom of the column (\( z = 1 \)). The boundary conditions were 98060 Pa of water pressure (atmospheric pressure) at the bottom of the column (\( z = 1 \)) combined with zero flux at the top (\( z = 0 \)), leading to upward infiltration against gravity. A numerical solution of this case using a 1D model has been presented by Vogel et al. (2001). The soil-water retention curve used was the modified Van Genuchten model. The same parameters were used as in the Vogel’s example:

- Porosity, \( n \): 0.38
- Hydraulic conductivity of water, \( K_w \): 5.56E-07 m/s or 4.8 cm/day
- Irreducible water saturation, \( S_{w0} \): 0.17895
- Van Genuchten’s \( a \) parameter: 0.8 1/m or 0.008 1/cm
- Van Genuchten’s \( n \) parameter: 1.09

Conversely to Vogel’s code, which used an adaptive time stepping algorithm, this code used a fixed timestep of 0.1 day. The 3D domain was a prismatic column of \( 0.2 \times 0.2 \times 1 \) m\(^3\). The mesh had 410 subdomains being finer in the bottom. Figure 1 presents a view of the mesh. Preliminary tests failed when a uniform mesh of 173 subdomains was used. In order to produce results equivalent to the 1D case, a zero flux boundary condition was imposed on the sides of the domain. In order to start the iterations of the non-linear loop in the first timestep, the code requires an initial guess for \( \tilde{p}_w \) different from zero within the domain, see Figure 2.

For the results presented in Figure 3, the initial guess was that \( \tilde{p}_w \) was equal to the initial conditions when \( z \leq 0.9 \) and from there the water pressure increased linearly up to the atmospheric pressure at \( z = 1 \), where it matched the boundary condition.
Figure 1: mesh of 410 subdomains.

Figure 2: Initial guess and initial condition for case 1.
The agreement of the results displayed in Figure 3 and those of Vogel et al. (2001) is very good.

Table 1 presents the number of iterations needed in every timestep to converge. Note how the convergence is easier as the pressure distribution becomes smoother.

6.2 CASE 2: Downward infiltration in clay

This example was used by Vogel et al. (2001). It is the simulation of infiltration in a 1m long clay column that, again, initially was assumed to be in equilibrium with an imposed water pressure, \( p_w \), of zero Pa at the bottom of the column. The boundary conditions were 98060 Pa of water pressure (atmospheric pressure) at the top of the column combined with zero flux at the bottom, leading to downward infiltration. Three meshes were used. The first one was identical to the one displayed in Figure 1, though the domain was inverted in order to have the finer part of the mesh in the top. The other two meshes, which had 1062 and a 2233 subdomains, are shown in Figure 4. The initial guess was a linear function of the \( z \)-coordinate that started with \( \tilde{p}_w \) = atmospheric pressure at \( z = 0 \) (top of the domain) and decreases to meet the initial condition curve at \( z = 0.1 \), from there the initial guess is identical to the initial condition. Figure 5 shows the initial guess and the initial condition. The remaining part of the set up was identical to case 1.
Figure 4: Case 2, view of the 1062 and 2233 subdomains meshes.

Figure 5: Initial guess and initial condition for case 2.

Figure 6 to Figure 8 show results using the three meshes described above. In Table 2 the number of iterations in every timestep is shown.
Figure 6: results of case 2 using the 410 subdomains mesh.

Figure 7: results of case 2 using the 1062 subdomains mesh.
Solving the downward infiltration case is more difficult than the upward infiltration case because the water goes down in a sharp front that resembles a step function. The severe non-linearity of the soil-water curve near saturation makes difficult computing the term \( \frac{1}{k_{rw}} \tilde{v} k_{rw} \) in (14), because in some points near saturation there are high values of \( \tilde{v} k_{rw} \) combined with very small values of \( k_{rw} \). Compared to case 1, when using the same mesh, the code needs more iterations to converge in the first 2 timesteps (see Table 2) and it does not converge in the third timestep within 150 iterations. The code was set to stop the iterative procedure after certain number of iterations (150 or 300) and these results are indicated in Table 2 as “truncated”. The situation improves with mesh refinement, as can be seen in Table 2. Mesh refinement improves only the convergence; the quality of the results is similar with different meshes, provided convergence has been reached. Compared to the results of Vogel et al., the agreement is not as good as in case 1.

7 CONCLUSIONS
A numerical model for flow in unsaturated media has been developed and solved using the
BEM DRM-MD approach. The model was developed in order to predict the saturation of clay in underground repositories, which requires solving two coupled non-linear partial differential equations; one for the air and one for the water phase. Taking into account that such a complex model can be solved in different ways, in order to study the basic behaviour of the formulation under simpler conditions before solving the full two phases model, the air was assumed to be at atmospheric pressure; a situation that is equivalent to solving the Richard’s equation.

The code showed that it is able to accurately solve problems of infiltration in clay. For instance, cases 1 and 2 showed an excellent performance in regard with the one-dimensional results of Vogel et al. (2001). However, there was slow convergence for downward infiltration. All the results indicate that the terms of the governing equation containing \( \frac{1}{k_{rw}} \nabla k_{rw} \) are the cause for slower convergence in some cases. The severe non-linearity of the soil-water curve near saturation makes the task of computing the term \( \frac{1}{k_{rw}} \nabla k_{rw} \) in (14) a very difficult one, because in some points near saturation there are high values of \( \nabla k_{rw} \) combined with very small values of \( k_{rw} \). The code loses accuracy when it has to calculate \( \nabla k_{rw} \) and the water advances in a sharp front that resembles a step function, as it happens in case 2. Case 2 shows that the problem can be resolved by using mesh refinement. However, mesh refinement in 3D increases much more computer requirements in terms of CPU and memory than in the cases of 1D and 2D.
